Preliminary

Abstract

The existing literature promotes a number of alternative methods to test for the presence of contagion during financial market crises. This paper reviews those methods, and shows how they are related in a unified framework. A number of extensions are also suggested which allow for multivariate testing, endogeneity issues and structural breaks.

Key words: Contagion.

JEL Classification: C15, F31

*This project was funded under ARC large grant A00001350. We are grateful to the many people who have provided enthusiasm to support this paper. The paper was partly written while Mardi Dungey was a Visiting Fellow at CERF. The authors contact details are: mardi.dungey@anu.edu.au; renee.fry@anu.edu.au; bgonzalez@imf.org; vance@unimelb.edu.au.
1 Introduction

There is now a reasonably large body of empirical work testing for the existence of contagion during financial crises. A range of different methodologies are in use, making it difficult to assess the evidence for and against contagion, and particularly its significance in transmitting crises between countries. In this paper, a simple framework shows how each of the methodologies are related and can in fact be expressed as a test of the significance of a slope dummy.1

The origins of current empirical studies of contagion stem from Sharpe (1964) and Grubel and Fadner (1971), and more recently from King and Wadhini (1990), Engle, Ito and Lin (1992) and Bekaert and Hodrick (1992). Many of the methods proposed in these papers are adapted in some form to the current empirical literature on measuring contagion.

The definition of the term contagion varies widely across the literature. In this paper contagion is represented by the transmission of unanticipated local shocks to another country, or market. This definition is consistent with both those of Masson (1998, 1999a,b), who divides shocks to asset markets as either common, spillovers that result from some identifiable channel, local or contagion, and as shown below that of other approaches, such as Forbes and Rigobon (2002) where contagion is represented by an increase in correlation during periods of crises.

Here, a simple framework based on a latent factor model shows how each of five methodologies in testing for contagion are related. The tests considered are nested within a latent factor framework proposed by the current authors in Dungey and Martin (2001) and similar to those of Corsetti, Pericoli and Sbracia (2001) and Bekaert, Harvey and Ng (2003). This framework is used to compare directly the correlation analysis approach popularised in this literature by Forbes and Rigobon (2002), the VAR approach of Giavazzi and Favero (2002), the use of co-exceedances as in Bae, Karolyi and Stulz (2003) and a probability based test similar to that of Eichengreen, Rose and Wyplosz (1995, 1996). The Forbes and Rigobon test is shown to be a test on a parameter in the latent factor framework, the VAR approach is a reorganisation of the same information, and the limited dependent variables approach involves a partial use of the same data with alternate conditioning information. Using a very general latent factor framework the relationships between these modelling approaches are directly constructed, and the nesting of the different tests becomes apparent.

1The literature on financial crises themselves is much wider than that canvassed here and is reviewed in Flood and Marion (1998) while more recent papers are represented by Allen and Gale (2000), Calvo and Mendoza (2000), Kyle and Xiong (2001) and Kodres and Pritsker (2002).
The paper proceeds as follows. In Section 2 a framework drawn from basic relationships between asset returns is used to model returns in a non-crisis environment. This framework is augmented in Section 3 to give a model which includes an avenue for contagion during a crisis. The relationship between this model and the correlation tests for contagion are examined in Section 4 which includes a generalisation of the Forbes and Rigobon bivariate test to a multivariate environment. The remaining non-linear tests are examined in Section 5 and additional methods are canvassed in Section 6. Each of the tests is shown to be a test of the significance of a slope dummy. Section 7 concludes.

2 A Model of Interdependence

Before developing a model of contagion, a model of interdependence of asset markets during non-crisis periods is specified as a latent factor model of asset returns. The model is related to the factor models in finance based on Arbitrage Pricing Theory for example, whereby asset returns are determined by a set of common factors and a set of idiosyncratic factors representing non-diversifiable risk. Similar latent factor models of contagion are used by Dungey and Martin (2001), Dungey, Fry, Gonzalez-Hermosillo and Martin (2002a), Forbes and Rigobon (2002) and Bekaert, Harvey and Ng (2003).

Let the returns of three asset markets during a non-crisis period be defined as

\[ \{x_{1,t}, x_{2,t}, x_{3,t}\} \]  

(1)

All returns are assumed to have zero means. The returns could be on currencies, or national equity markets, or a combination of currency and equity return in a particular country or across countries. The following trivariate factor model is assumed to summarise the dynamics of the three processes during a period of tranquility

\[ x_{i,t} = \lambda_i w_t + \delta_i u_{i,t}, \quad i = 1, 2, 3. \]  

(2)

The variable \( w_t \) represents common shocks that impact upon all asset returns with loadings \( \lambda_i \). These shocks could represent financial shocks arising from changes to the risk aversion of international investors, or changes in world endowments (Mahieu and Schotman (1994), Rigobon (2003)). In general, \( w_t \) represents market fundamentals which determine the average level of asset returns across international markets during “normal”, that is, tranquil, times. This variable is commonly referred to as a world factor, which may or may not be observed. For simplicity, the world factor is assumed to be a latent stochastic process with zero mean and unit variance

\[ w_t \sim (0, 1). \]  

(3)
The properties of this factor are extended below to capture richer dynamics including both autocorrelation and time-varying volatility. The terms $u_{i,t}$ in equation (2) are idiosyncratic factors that are unique to a specific asset market. The contribution of idiosyncratic shocks to the volatility of asset markets is determined by the loadings $\delta_i > 0$. These factors are also assumed to be stochastic processes with zero mean and unit variance

$$u_{i,t} \sim (0, 1).$$

To complete the specification of the model, all factors are assumed to be independent

$$E[u_{i,t}, u_{j,t}] = 0, \quad \forall i \neq j$$
$$E[u_{i,t}, w_t] = 0, \quad \forall i.$$  

To highlight the interrelationships amongst the three asset returns in (2) during a non-crisis period, the covariances are given by

$$E[x_{i,t}, x_{j,t}] = \lambda_i \lambda_j, \quad \forall i \neq j,$$

whilst the variances are

$$E[x_{i,t}^2] = \lambda_i^2 + \delta_i^2 \quad \forall i.$$  

Expression (7) shows that any dependence between asset returns is solely the result of the influence of common shocks arising from $w_t$, that simultaneously impact upon all markets. Setting

$$\lambda_1 = \lambda_2 = \lambda_3,$$  

results in independent asset markets with all movements determined by the idiosyncratic shocks, $u_{i,t}$.\footnote{Of course, just two of the restrictions in (7) are sufficient for independence of asset markets.}

3 Unanticipated Shock Models of Contagion

Dungey, Fry, Gonzalez-Hermosillo and Martin (2002a,b) define contagion as the effects of unanticipated shocks across asset markets during a period of crisis. To distinguish between asset returns in a non-crisis and crisis periods, $y_{i,t}$ represents the return during the crisis period and $x_{i,t}$ the return during the non-crisis period.
Consider the case of contagion from country 1 to country 2. The factor model in (2) is now augmented as follows

\[ y_{1,t} = \lambda_1 w_t + \delta_1 u_{1,t} \]
\[ y_{2,t} = \lambda_2 w_t + \delta_2 u_{2,t} + \gamma u_{1,t} \]
\[ y_{3,t} = \lambda_3 w_t + \delta_3 u_{3,t} , \]

where the \( x_{i,t} \) are replaced by \( y_{i,t} \) to signify demeaned asset returns during the crisis period. The expression for \( y_{2,t} \) now contains a contagious transmission channel as represented by unanticipated local shocks from the asset market in country 1, with its impact measured by the parameter \( \gamma \). An important assumption underlying (10) is that the common shock and idiosyncratic shocks have the same impact during the crisis period as they do have during the non-crisis period. This assumption is discussed in Section 3.3.

### 3.1 Bivariate Testing

From (10), the covariance between the asset returns of countries 1 and 2 during the crisis is

\[ E[y_{1,t}y_{2,t}] = \lambda_1 \lambda_2 + \gamma \delta_1 . \] (11)

Comparing this expression with the covariance for the pre-crisis period in (7) shows that the change in covariance between the two periods is

\[ E[y_{1,t}y_{2,t}] - E[x_{1,t}x_{2,t}] = \gamma \delta_1 . \] (12)

If \( \gamma > 0 \), there is an increase in the covariance of asset returns during the crisis period as \( \delta_1 > 0 \) by assumption. This is usually the situation observed in the data. However, it is possible for \( \gamma < 0 \), in which case there is a reduction in the covariance. Both situations are valid as both represent evidence of contagion via the impact of unanticipated shocks in (10). Hence a test of contagion is given by testing the restriction

\[ \gamma = 0 , \] (13)

in the factor model (10). This is the approach adopted by Dungey and Martin (2002) and Dungey, Fry, Gonzalez-Hermosillo and Martin (2002a,b, 2003).\(^3\)

\(^3\)Most concern seems to centre on the case where \( \gamma > 0 \), that is where contagion is associated with a rise in volatility. The existing tests can be characterised as variously distinguish testing the null hypothesis of \( \gamma = 0 \) against the two-sided or one-sided alternative.
An alternative way to construct a test of contagion is to use the volatility expression for \( y_{2,t} \), which is given by

\[
E y_{2,t}^2 = \lambda_2^2 + \delta_2^2 + \gamma_2^2.
\]

As the change in volatility over the two periods is solely attributed to the presence of contagion

\[
E y_{2,t}^2 - E x_{2,t}^2 = \gamma_2^2;
\]

the contagion test based on (13) can be interpreted as a test of whether there is an increase in volatility. The expression (14) suggests that a useful decomposition of the volatility of \( y_{2,t} \) is to decompose the effects of shocks into global, idiosyncratic and contagion as follows

\[
\frac{\lambda_1^2}{\lambda_2^2 + \delta_2^2 + \gamma_2^2}, \frac{\delta_2^2}{\lambda_2^2 + \delta_2^2 + \gamma_2^2}, \frac{\gamma_2^2}{\lambda_2^2 + \delta_2^2 + \gamma_2^2}.
\]

This decomposition provides a descriptive measure of the relative strength of contagion in contributing to volatility. As before, the strength of contagion is determined by the parameter \( \gamma \), which can be tested formally.

### 3.2 Multivariate Testing

The test for contagion presented so far is a test for contagion from country 1 to country 2. However, it is possible to test for contagion in all directions by writing (10) as

\[
\begin{align*}
y_{1,t} &= \lambda_1 w_t + \delta_1 u_{1,t} + \gamma_{1,2} u_{2,t} + \gamma_{1,3} u_{3,t} \\
y_{2,t} &= \lambda_2 w_t + \delta_2 u_{2,t} + \gamma_{2,1} u_{1,t} + \gamma_{2,3} u_{3,t} \\
y_{3,t} &= \lambda_3 w_t + \delta_3 u_{3,t} + \gamma_{3,1} u_{1,t} + \gamma_{3,2} u_{2,t},
\end{align*}
\]

or more succinctly

\[
y_{i,t} = \lambda_i w_t + \delta_i u_{i,t} + \sum_{j=1, j \neq i}^{3} \gamma_{i,j} u_{j,t}.
\]

In this case there are 6 parameters, \( \gamma_{i,j} \), controlling the strength of contagion across all asset markets. This model, by itself, is unidentified as there are 12 unknown parameters. However, by combining the empirical moments of the variance-covariance matrix during the crisis period, 6 moments, from the empirical moments from the variance-covariance matrix of the pre-crisis period in (??), another 6 moments, gives 12 empirical moments in total which can be used to identify the 12 unknown parameters.
A joint test of contagion using the factor model in (2) and (17), can be achieved by comparing the objective function from the unconstrained model, \( q_u \), with the value obtained from estimating the constrained model, \( q_c \), whereby the contagion parameters are set to zero. As the unconstrained model is just identified, \( q_u = 0 \), in which case the test is simply a test that under the null hypothesis of no contagion

\[ H_0 : q_c = 0, \]  
(19)

which is distributed asymptotically as \( \chi^2 \) with 6 degrees of freedom under the null. As before, the test of contagion can be interpreted as testing for changes in both variances and covariances.

### 3.3 Structural Breaks

The model given by equations (2) and (18) is based on the assumption that the increase in volatility during the crisis period is solely generated by contagion, that is, \( \gamma_{i,j} \neq 0 \forall i, j \). However, another scenario is that there is a general increase in volatility without any contagion; denoted as increased interdependence by Forbes and Rigobon (2002). This would arise if either the world loadings \( (\lambda_i) \) change, or idiosyncratic loadings \( (\delta_i) \) change, or a combination of the two. The former would be representative of a general increase in volatility across all asset markets brought about for example, by an increase in the risk aversion of international investors. The latter would arise from increases in the shocks of (some) individual asset markets which are entirely specific to those markets and thus independent of other asset markets.

To allow for structural breaks in the underlying relationships the number of contagious linkages that can be entertained needs to be restricted. In the case where changes in the idiosyncratic shocks are allowed across the sample periods in all \( N \) asset markets, equation (18) becomes

\[ y_{i,t} = \lambda_i w_t + \delta_{y,i} u_{i,t} + \sum_{j=1, j \neq i}^{3N} \gamma_{i,j} u_{j,t}, \]  
(20)

where \( \delta_{y,i} \neq \delta_i \), are the idiosyncratic parameters during the crisis period. Bekaert, Harvey and Ng (2003) adopt a different strategy for modelling structural breaks by specifying time varying factor loadings.

The number of world and idiosyncratic parameters now increases to \( 3N \). Because the model is still block-recursive, there are just \( N (N + 1) / 2 \) empirical moments from the crisis period available to identify the contagion parameters \( \gamma_{i,j} \) and the structural
break parameters \((\delta_{y,i})\). This means that there are \(N(N + 1)/2 - N = N(N - 1)/2\), excess moments to identify contagion channels.

Extending the model to allow for structural breaks in both global and idiosyncratic factors in all \(N\) asset markets, increases the number of world and idiosyncratic parameters to \(4N\), now yielding \(N(N + 1)/2 - 2N = N(N - 3)/2\), excess moments to identify contagion channels in the crisis period. For a trivariate model \((N = 3)\) that allow for all potential structural breaks in world and idiosyncratic factors, no contagion channels can be tested as the model is just identified. Extending the model to \(N = 4\), assets, allows for \(N(N - 3)/2 = 2\) potential contagion channels. Further extending the model to \(N = 6\) assets, means that the number of contagion channels that can be tested increases to \(N(N - 3)/2 = 9\).

In general, an allowance for both contagion and structural breaks results in identification problems if the number of structural breaks entertained is unrestricted. To highlight this point, consider the following bivariate model without contagion, but with a structural break in the world factor. The model over the pre-crisis period is specified as before

\[
x_{1,t} = \lambda_{1}w_{t} + \delta_{1}u_{1,t} \tag{21}
\]
\[
x_{2,t} = \lambda_{2}w_{t} + \delta_{2}u_{2,t},
\]

whilst the model over the crisis period is now specified as

\[
y_{1,t} = \lambda_{y,1}w_{t} + \delta_{1}u_{1,t} \tag{22}
\]
\[
y_{2,t} = \lambda_{y,2}w_{t} + \delta_{2}u_{2,t}.
\]

The parameters \(\lambda_{y,1} \neq \lambda_{1}\) and \(\lambda_{y,2} \neq \lambda_{2}\), are the structural break parameters. This model is just identified with the 6 unknown parameters being jointly identified by the 6 empirical moments obtained from the variance-covariance matrices from the two sub-periods. One characteristic of this model is that the excess moments all change over the two periods

\[
E \left[ y_{1,t}^{2} \right] - E \left[ x_{1,t}^{2} \right] = \lambda_{y,1}^{2} - \lambda_{1}^{2}
\]
\[
E \left[ y_{2,t}^{2} \right] - E \left[ x_{2,t}^{2} \right] = \lambda_{y,2}^{2} - \lambda_{2}^{2} \tag{23}
\]
\[
E \left[ y_{1,t}y_{2,t} \right] - E \left[ x_{1,t}x_{2,t} \right] = \lambda_{y,1}\lambda_{y,2} - \lambda_{1}\lambda_{2}.
\]

But, the properties of this model are exactly the same as a model with contagion running in both directions, such as equation (18), as all of the second moments of this model also change over time. That is, the two models are observationally equivalent and cannot be identified separately.
3.4 Using Just Crisis Data

Identification of the unknown parameters in the factor model framework discussed above is based on using information on both non-crisis and crisis periods. However, there may be a problem for certain asset markets in using non-crisis data to obtain empirical moments to identify unknown parameters, such as for example in the move from fixed to floating exchange rate regimes during the East Asian currency crisis. However, it is possible to identify the model using just crisis period data, provided that the number of asset returns exceeds 3 and a limited number of contagious links are entertained. For example, increasing the number of asset returns to 4, provides 10 unique empirical moments from the variance-covariance matrix using crisis data. Specifying the factor model in (2) for \( N = 4 \) assets, means that there are 4 world parameters and 4 idiosyncratic parameters. This suggests that 2 contagious links can be specified and identified.

3.5 Autoregressive and Heteroskedastic Dynamics

The factor model can be extended to include autoregressive dynamics. Two avenues are possible. The first consists of specifying the world factor to follow for an autoregressive structure. In the case of an AR(1) model then

\[
w_t = \theta w_{t-1} + \eta_{w,t},
\]

(24)

where \( \eta_{w,t} \) is a disturbance term with zero mean and constant variance. Combining (24) with (??) and (??) yields a state-space model which can be estimated using a Kalman filter, for example. In this case, a joint test of contagion is conveniently performed by using a likelihood ratio test, or some other likelihood based testing procedure.

The implications of (24) for the dynamics of asset returns is highlighted in the case of asset returns during the pre-crisis period, by rewriting (2) as

\[
(1 - \theta w L) x_{i,t} = \lambda_i (1 - \theta w L) w_t + \delta_i (1 - \theta w L) u_{i,t}
\]

\[
= \lambda_i \eta_{w,t} + \delta_i (1 - \theta w L) u_{i,t}
\]

\[
= \varepsilon_{i,t},
\]

where \( L^k z_t = z_{t-k} \) defines the lag operator, and \( \varepsilon_{i,t} \) is a composite disturbance term that has a MA(1) structure. Combining all \( N = 3 \) equations and inverting the moving average, yields a VAR where there are a number of cross-equation restrictions on the parameters of the lagged variables. Thus the factor model represents a restricted VAR. This property is particularly appealing in the context of multivariate tests of contagion.
as the factor structure provides a parsimonious representation of the data thereby
circumventing the usual degrees of freedom issues associated with even moderate sized
VARs.

The second way to introduce dynamics into the model is to specify an autoregressive
structure for the idiosyncratic factors, such as the following AR(1) structure

$$u_{i,t} = \theta_i u_{i,t-1} + \eta_{i,t},$$

(25)

where $\eta_{i,t}$ are disturbance terms with zero mean and constant variance. More generally,
both (24) and (25) can be specified to capture the dynamics of asset returns, resulting
in a general state-space representation which can be estimated using a Kalman filter.

Autocorrelation is relatively unlikely in asset returns. A potentially more important
class of dynamics arises from changes in the volatility structure. This is especially true
in models of contagion as increases in volatility are symptomatic of crises.

The discussion of structural breaks in the underlying relationships across the sample
period represents one form of change in volatility. The form of this type of heteroskedastic-
ticity is given by a deterministic shift in the variance across the sample period. More
generally, the conditional volatility can be expected to vary systematically over time
and not just in a discrete jump. A natural way to capture this phenomenon is to
include a GARCH structure on the factors. In the case where there is a single factor,
a suitable specification is

$$w_t = e_t,$$

(26)

where

$$e_t \sim N (0, h_t),$$

(27)

with conditional volatility $h_t$, given by a GARCH factor structure (Diebold and Nerlove

$$h_t = (1 - \alpha - \beta) + \alpha e_{t-1}^2 + \beta h_{t-1}.$$

(28)

The choice of the normalisation $(1 - \alpha - \beta)$, constrains the unconditional volatility to
equal unity and is adopted for identification.

For example, using (10) augmented by (26) to (28), total (conditional) volatility of
$y_{2,t}$, the asset return in the crisis period, is now given by

$$E_{t-1} \frac{\mathbb{E}}{y_{2,t}^2} = E_{t-1} \left( \lambda_2 w_t + \delta_2 u_{2,t} + \gamma u_{1,t} \right)^2$$

$$= \lambda_2^2 h_t + \delta_2^2 + \gamma^2,$$

10
where the assumption of independence in (5) and (6) is utilised. The conditional covariance between $y_{1,t}$ and $y_{2,t}$ during the crisis period for example, is
\[
E_{t-1}[y_{1,t}y_{2,t}] = E_{t-1}[(\lambda_1 w_t + \delta_1 u_{1,t})(\lambda_2 w_t + \delta_2 u_{2,t} + \gamma u_{1,t})] \\
= \lambda_1 \lambda_2 h_t + \gamma \delta_1.
\]
Both the conditional variance and covariance during the crisis period are affected by the presence of contagion ($\gamma \neq 0$). In particular, contagion has the effect of causing a structural shift during the crisis period in the conditional covariance by $\gamma \delta_1$, and the conditional variance by $\gamma^2$.

The inclusion of a GARCH world factor into an N factor model of asset returns provides a parsimonious multivariate GARCH model. This model, when combined with a model of contagion, can capture changes in the variance and covariance structures of asset returns during financial crises. The parsimony of the factor GARCH model specification contrasts with multivariate GARCH models based on the BEKK specification (Engle and Kroner (1995) which require a large number of parameters for even moderate size models.4 Methods for estimating factor GARCH models in the context of contagion are discussed by Dungey and Martin (2002), Dungey, Fry, Gonzalez-Hermosillo and Martin (2002a, 2003) and Bekaert, Harvey and Ng (2003).

4 Correlation and Covariance Analysis

Forbes and Rigobon (2002) define contagion as the increase in correlation between two variables during a crisis period. In performing their test, the correlation between the two asset returns during the crisis period is adjusted to overcome the problem that correlations are a positive function of volatility. As crisis periods are typically characterised by an increase in volatility, a test based on the (conditional) correlation is biased upwards resulting in evidence of spurious contagion. Butler and Joaquin (2002) conduct the same test across bull and bear markets, although they do not specifically use the terminology of contagion.

A feature of the correlation applications is that they are based on pair-wise comparisons and thus do not consider potential multivariate analogues of the test. To overcome this problem, a multivariate approach is proposed below based on simple regression equations augmented by dummy variables. This extension stems from the insight that the adjustments to the correlation coefficients proposed by Forbes and Rigobon (2002) provide a parsimonious multivariate GARCH model.
Rigobon can be placed conveniently within a bivariate regression framework where the underlying variables are scaled appropriately.

### 4.1 Bivariate Testing

To demonstrate the Forbes and Rigobon (2002) approach, consider testing for contagion from country 1 to country 2. The correlation between the asset returns of the two asset markets is \( \rho_y \) during the crisis period (high volatility period) and \( \rho_x \) in the pre-crisis (low volatility period).\(^5\) If there is an increase in the volatility in the asset return of country 1, \( \sigma_{y,1}^2 > \sigma_{x,1}^2 \), without there being any change to the fundamental relationship between the asset returns in the two markets, then \( \rho_y > \rho_x \), giving the false appearance of contagion. To adjust for this bias, Forbes and Rigobon show that the adjusted (unconditional) correlation is given by; see also Boyer, Gibson and Loretan (1999); and Loretan and English (2000)\(^6\)

\[
\nu_y = \frac{\rho_y}{1 + \frac{\sigma_{y,1}^2 - \sigma_{x,1}^2}{\sigma_{x,1}^2} \left( 1 - \rho_y^2 \right)} \tag{29}
\]

This is the unconditional correlation \( \nu_y \) which is the conditional correlation scaled by a nonlinear function of the percentage change in volatility in the asset return of the source country \( \frac{\sigma_{y,1}^2 - \sigma_{x,1}^2}{\sigma_{x,1}^2} \), country 1 in this case, over the high and low volatility periods. This adjustment allows for a levels shift in the volatility of asset 1, whereby \( \nu_y = \rho_x \) if there is no fundamental change in the relationship between the two asset markets.

To test that there is a significant change in correlation, the null hypothesis is

\[
H_0 : \nu_y = \rho_x \tag{30}
\]

against the alternative hypothesis of

\[
H_1 : \nu_y > \rho_x \tag{31}
\]

A t-statistic for testing these hypothesis is given by

\[
FR_1 = \frac{b_y - b_x}{\frac{1}{T_y} + \frac{1}{T_x}} \tag{32}
\]

\(^5\)Forbes and Rigobon (2002) in their empirical application, compare the crisis period correlation with the correlation calculated over the total sample period (low volatility period). That is, \( x \) is replaced by \( z = (x; y) \). This alternative formulation is also discussed below.

\(^6\)Other approaches using correlation analysis are Karolyi and Stultz (1996) and Longin and Solnik (1995).
where the ^ signifies the sample estimator, and \( T_y \) and \( T_x \) are the respective sample sizes of the high volatility and low volatility periods. The standard error in (32) derives from the asymptotic distribution of the estimated correlation coefficient. To improve the finite sample properties of the test statistic, Forbes and Rigobon (2002) suggest using the Fisher transformation\(^7\)

\[
FR_2 = \frac{1}{2} \ln \frac{1 + b_y}{1 - b_y} - \frac{1}{2} \ln \frac{1 + b_x}{1 - b_x},
\]

(33)

### 4.2 Alternative Formulation

In implementing the correlation test in (33), equation (29) shows that the conditional correlation needs to be scaled initially by a nonlinear function of the change in volatility in the asset return of the source country, country 1 in this case, over the pertinent sample periods. Another way to implement the Forbes and Rigobon test of contagion is to scale the asset returns and perform the contagion test within a regression framework.\(^8\) Continuing with the example of testing for contagion from the asset market of country 1 to the asset market of country 2, consider scaling the asset returns during the pre-crisis period by their respective standard deviations. First define the following regression equation in terms of the scaled asset returns

\[
\frac{\mu_{x_2,t}}{\sigma_{x_2}} = \alpha_0 + \alpha_1 \frac{\mu_{x_1,t}}{\sigma_{x_1}} + \eta_{x,t},
\]

(34)

where \( \eta_{x,t} \) is a disturbance term and \( \alpha_0 \) and \( \alpha_1 \) are regression parameters. The pre-crisis slope regression parameter is related to the pre-crisis correlation coefficient as \( \alpha_1 = \rho_x \). For the crisis returns the regression equation is given as follows, where the scaling of asset returns is still by the respective standard deviations from the pre-crisis periods

\[
\frac{\mu_{y_2,t}}{\sigma_{x_2}} = \beta_0 + \beta_1 \frac{\mu_{y_1,t}}{\sigma_{x_1}} + \eta_{y,t},
\]

(35)

\(^7\)This transformation is valid for small values of the correlation coefficients, \( \rho_x \) and \( \nu_y \). Further refinements are discussed in Kendall and Stuart (1969, Vol.1, p.391). For the case of independence, \( \rho_x = \nu_y = 0 \), an exact expression for the variance of the transformed correlation coefficient is available. An illustration of these problems for the Forbes and Rigobon method is given in Dungey and Zhumabekova (2001).

\(^8\)Corsetti, Pericoli and Sbracia (2001) extend the Forbes and Rigobon framework to a model equivalent to the factor structure given in (10). Their approach requires evaluating quantities given by the ratio of the contribution of idiosyncratic and common factors to volatility, \( \delta^2 / \lambda^2 \) for example. These quantities can be estimated directly using the framework discussed in Section 2.2.
where $\eta_{y,t}$ is a disturbance term and $\beta_0$ and $\beta_1$ are regression parameters. The crisis regression slope parameter $\beta_1 = \nu_y$, which is the Forbes-Rigobon adjusted correlation coefficient given in (29).

This alternative formulation suggests that another way to implement the Forbes-Rigobon adjusted correlation is to estimate (34) and (35) by OLS and test the equality of the regression slope parameters. This test is equivalent to a Chow test for a structural break of the regression slope. Implementation of the test can be based on the following pooled regression equation over the entire sample

$$\frac{\mu_{z,t}}{\sigma_{x,2}} = \gamma_0 + \gamma_1 d_t + \gamma_2 \frac{\mu_{z_1,t}}{\sigma_{x,1}} + \gamma_3 \frac{\mu_{z_1,t}}{\sigma_{x,1}} d_t + \eta_t,$$  

(36)

where

$$z_i = i \cdot x_{i,1}, x_{i,2}, \ldots, x_{i,T_x}, y_{i,1}, y_{i,2}, \ldots, y_{i,T_y} \quad \xi,$$

(37)

represents the $(T_x + T_y) \times 1$ scaled pooled data set by stacking the pre-crisis and crisis scaled data, $d_t$ is a slope dummy variable defined as

$$d_t = \begin{cases} 1 & : t > T_x \\ 0 & : \text{otherwise} \end{cases},$$

(38)

and $\eta_t$ is a disturbance term. The parameter $\gamma_3 = \beta_1 - \alpha_1$ in (36), captures the effect of contagion. It represents the additional contribution of information on asset returns in country 2 to the pre-crisis regression: if there is no change in the relationship the dummy variable provides no new additional information during the crisis period, resulting in $\gamma_3 = 0$. Thus the Forbes and Rigobon contagion test can be implemented by estimating (36) by OLS and performing a one-sided t-test of

$$H_0 : \gamma_3 = 0,$$

(39)

in (36), which is equivalent to testing

$$H_0 : \alpha_1 = \beta_1,$$

(40)

in (34) and (35).9 Of course, the test statistic to perform the contagion test is invariant to scaling transformations of the regressors, such as the use of $\sigma_{x,1}$ and $\sigma_{x,2}$ to standardise $z_i$. This would suggest that an even more direct way to test for contagion

\[9\]Interestingly, Caporale, Cipollini and Spagnolo (2002), conduct a test of contagion based on a slope dummy, but do not identify the connection of the test with the Forbes and Rigobon (2002) correlation approach.
would have been to have implemented a standard test of parameter constancy in a regression framework simply based on $z_t$, the unscaled data.\footnote{To implement the form of the Forbes and Rigobon (2002) version of the correlation test within the regression framework in (36), the pre-crisis data is now replaced by the total sample data. That is, the low volatility period is defined as the total sample period and not the pre-crisis period. This requires redefining the pertinent variables as $z_t = (x, y, y, \ldots)$ and the slope dummy as $d = \begin{pmatrix} 1 & 1 & 1 & \ldots \end{pmatrix}^T$, and scaling the variables in $z_t$ by the respective standard deviations obtained from the total sample period $(x, y, \ldots)$.}

There is one difference between the regression approach to correlation testing for contagion based on (36) and the Forbes and Rigobon approach, and that is the standard errors used in the test statistics are different in small samples. The latter approach is based on the small sample asymptotic adjustment given in (33), whilst the former are based in general, on the usual least squares standard errors.

### 4.3 Multivariate Testing

The regression framework developed above for implementing the Forbes and Rigobon test suggests that a multivariate analogue can be easily constructed as follows:\footnote{As will become apparent, issues of endogeneity immediately arise. These issues are discussed below.} To simplify the analysis, it is assumed that the data are demeaned over the pertinent sample periods, so intercepts and intercept dummy variables are excluded from the regression specifications. In the case of three asset returns, the pre-crisis period equations are

\[
\begin{align*}
\mu_{x_{1,t}} &= \alpha_{1,2} \frac{\mu_{x_{2,t}}}{\sigma_{x,1}} + \alpha_{1,3} \frac{\mu_{x_{3,t}}}{\sigma_{x,3}} + \eta_{x,1,t} \\
\mu_{x_{2,t}} &= \alpha_{2,1} \frac{\mu_{x_{1,t}}}{\sigma_{x,2}} + \alpha_{2,3} \frac{\mu_{x_{3,t}}}{\sigma_{x,3}} + \eta_{x,2,t} \\
\mu_{x_{3,t}} &= \alpha_{3,1} \frac{\mu_{x_{1,t}}}{\sigma_{x,1}} + \alpha_{3,2} \frac{\mu_{x_{2,t}}}{\sigma_{x,2}} + \eta_{x,3,t},
\end{align*}
\]

whilst the crisis equations are specified as

\[
\begin{align*}
\mu_{y_{1,t}} &= \beta_{1,2} \frac{\mu_{y_{2,t}}}{\sigma_{x,1}} + \beta_{1,3} \frac{\mu_{y_{3,t}}}{\sigma_{x,3}} + \eta_{y,1,t} \\
\mu_{y_{2,t}} &= \beta_{2,1} \frac{\mu_{y_{1,t}}}{\sigma_{x,2}} + \beta_{2,3} \frac{\mu_{y_{3,t}}}{\sigma_{x,3}} + \eta_{y,2,t} \\
\mu_{y_{3,t}} &= \beta_{3,1} \frac{\mu_{y_{1,t}}}{\sigma_{x,1}} + \beta_{3,2} \frac{\mu_{y_{2,t}}}{\sigma_{x,2}} + \eta_{y,3,t}.
\end{align*}
\]

A joint test of contagion is given by

\[
\alpha_{i,j} = \beta_{i,j}, \quad \forall i \neq j,
\]
which represents 6 restrictions. A convenient way to implement the multivariate version of the Forbes and Rigobon test is to adopt the strategy of (36) and write the model as a 3 equation system augmented by a set of slope dummy variables to capture the impact of contagion on asset returns

\[
\begin{align*}
\mu_{z_1,t} &= \alpha_{1,2} \mu_{z_2,t} + \alpha_{1,3} \mu_{z_3,t} + \gamma_{1,2} \frac{\sigma_{z_2,t}}{\sigma_{x,1}} \mu_{d_t} + \gamma_{1,3} \frac{\sigma_{z_3,t}}{\sigma_{x,1}} \mu_{d_t} + \eta_{1,t} \\
\mu_{z_2,t} &= \alpha_{2,1} \mu_{z_1,t} + \alpha_{2,3} \mu_{z_3,t} + \gamma_{2,1} \frac{\sigma_{z_1,t}}{\sigma_{x,2}} \mu_{d_t} + \gamma_{2,3} \frac{\sigma_{z_3,t}}{\sigma_{x,2}} \mu_{d_t} + \eta_{2,t} \\
\mu_{z_3,t} &= \alpha_{3,1} \mu_{z_1,t} + \alpha_{3,2} \mu_{z_2,t} + \gamma_{3,1} \frac{\sigma_{z_1,t}}{\sigma_{x,3}} \mu_{d_t} + \gamma_{3,2} \frac{\sigma_{z_2,t}}{\sigma_{x,3}} \mu_{d_t} + \eta_{3,t}
\end{align*}
\]

where the \( z_i \) pooled asset returns are as defined in (37), \( \eta_i \) are disturbance terms, \( d_t \) is the dummy variable defined in (38), and \( \gamma_{i,j} = \beta_{i,j} - \alpha_{i,j} \), are the parameters which control the strength of contagion.

The multivariate contagion test is based on testing the null hypothesis

\[
H_0: \gamma_{i,j} = 0, \quad \forall i \neq j.
\]

Implementation of the test can be performed by using standard multivariate test statistics, including likelihood ratio, Wald and Lagrange multiplier.

Rigobon (2003) suggests an alternative multivariate test of contagion. This test is referred to as the determinant of the change in the covariance matrix (DCC) as it is based on comparing the covariance matrices across two samples and then taking the determinant to express the statistic as a scalar. The DCC statistic is formally defined as

\[
DCC = \frac{\mathbf{b}_y - \mathbf{b}_x}{\mathbf{b}_{DCC}},
\]

where \( \mathbf{b}_y \) and \( \mathbf{b}_x \) are respectively the estimated covariance matrices of asset returns in the crisis and pre-crisis periods respectively, and \( \mathbf{b}_{DCC} \) is an estimate of the pertinent standard error of the statistic. Under the null hypothesis there is no change in the covariance structure of asset returns across sample periods, resulting in a value of \( DCC = 0 \). If contagion increases volatility during the crisis period, then \( DCC > 0 \), resulting in a rejection of the null hypothesis of no contagion.

The DCC test represents a test of parameter stability and thus provides an alternative test to a Chow test. However, given the relationship between Chow and contagion tests discussed above, this implies that potentially the DCC test is also a test of contagion. To highlight this point, consider the following bivariate factor model based on
the first two equations in (2) and (10). The pre-crisis and crisis covariance matrices are respectively

\[ \Omega_x = \begin{pmatrix} \lambda_1^2 + \delta_1^2 & \lambda_1 \lambda_2 \\ \lambda_1 \lambda_2 & \lambda_2^2 + \delta_2^2 \end{pmatrix}, \quad \Omega_y = \begin{pmatrix} \lambda_1^2 + \delta_1^2 & \lambda_1 \lambda_2 + \gamma \delta_1 \\ \lambda_1 \lambda_2 + \gamma \delta_1 & \lambda_2^2 + \delta_2^2 + \gamma^2 \end{pmatrix}. \]

The numerator of the DCC statistic is this case is

\[ \bar{\Omega}_y - \hat{\Omega}_x = \begin{pmatrix} 0 & b \bar{b}_1 \\ b \bar{b}_1 & b^2 \end{pmatrix} = b^2 \hat{b}_1, \]

where the \( \hat{\cdot} \) signifies a parameter estimator. Under the null hypothesis \( DCC = 0 \), which is achieved when \( \gamma = 0 \), a result that is equivalent to the tests of contagion already discussed.

In implementing the DCC test, the covariance matrices employed tend to be conditional covariance matrices if dynamics arising from lagged variables and other exogenous variables are controlled for. The simplest approach is to estimate a VAR for the total period, \( T_x + T_y \), and base the covariances on the VAR residuals. This is the approach adopted in the empirical application of Rigobon (2003). The advantage of working with VAR residuals, as compared to structural residuals, is that the VAR represents an unconstrained reduced form, thereby circumventing problems of simultaneity bias. These issues are now discussed.

4.4 Endogeneity Issues

The potential simultaneity biases arising from the presence of endogenous variables are more evident when the Forbes and Rigobon test is case in a linear regression framework. Forbes and Rigobon perform the correlation test in pairs of countries under the assumption that contagion spreads from one country to another with the source country being exogenous. The test can then be performed in the reverse direction with the implicit assumption of exogeneity on the two asset returns reversed. Performing the two tests in this way is inappropriate as it clearly ignores the simultaneity bias problem.\(^\text{12}\)

Forbes and Rigobon (2002) show using a Monte Carlo analysis that the size of the simultaneity bias is unlikely to be severe if the size of the correlations between asset returns are relatively small. Interestingly, Rigobon (2003) notes that the volatility adjustment in performing the test in (29) is incorrect in the presence of simultaneity bias. However, as noted above, the Forbes and Rigobon adjustment acts as a scaling

\(^{12}\)Forbes and Rigobon recognise this problem and do not test for contagion in both directions being very clear about their exogeneity assumptions.
parameter which has no affect on the properties of the test statistic in a linear regression framework. The problem of simultaneity bias is the same whether the endogenous explanatory variables are scaled or not.

To perform the Forbes and Rigobon contagion test while correcting for simultaneity bias, equations (41) and (42) need to be estimated initially using a simultaneous equations estimator and the tests of contagion performed on the simultaneous equation estimates of $\gamma_{i,j}$ in (44). To demonstrate some of the issues, the bivariate model in (34) and (35) is expanded to allow for structural breaks in the idiosyncratic loadings. The bivariate version of the model without intercepts during the pre-crisis and crisis periods are respectively (where for clarity, $\varrho_{i,t} = \eta_{x,i,t}$ and $\xi_{i,t} = \eta_{y,i,t}$ in comparison with equations (34) and (35))

$$
\begin{align*}
\mu_{x1,t} &= \frac{\alpha_1 \sigma_{x1}^2}{1 - \alpha_1 \alpha_2} + \varrho_{1,t} \\
\mu_{x2,t} &= \frac{\alpha_2 \sigma_{x2}^2}{1 - \alpha_1 \alpha_2} + \varrho_{2,t},
\end{align*}
$$

(47)

(48)

where $\varrho_{i,t}$ are iid with zero means and variances $E \xi_{\varrho,i}^2$, and

$$
\begin{align*}
\mu_{y1,t} &= \frac{\beta_1 \sigma_{y1}^2}{1 - \beta_1 \beta_2} + \xi_{1,t} \\
\mu_{y2,t} &= \frac{\beta_2 \sigma_{y2}^2}{1 - \beta_1 \beta_2} + \xi_{2,t},
\end{align*}
$$

(49)

(50)

where $\xi_{i,t}$ are iid with zero means and variances $E \xi_{\varrho,i}^2$. The respective reduced forms are

$$
\begin{align*}
\mu_{x1,t} &= \frac{1}{1 - \alpha_1 \alpha_2} \varrho_{1,t} + \alpha_1 \varrho_{2,t} \\
\mu_{x2,t} &= \frac{1}{1 - \alpha_1 \alpha_2} \varrho_{2,t} + \alpha_2 \varrho_{1,t},
\end{align*}
$$

(51)

for the pre-crisis period and

$$
\begin{align*}
\mu_{y1,t} &= \frac{1}{1 - \beta_1 \beta_2} \xi_{1,t} + \beta_1 \xi_{2,t} \\
\mu_{y2,t} &= \frac{1}{1 - \beta_1 \beta_2} \xi_{2,t} + \beta_2 \xi_{1,t},
\end{align*}
$$

(52)

for the crisis period. For the two sub-periods the variance-covariance matrices are

$$
\begin{align*}
\Omega_x &= \frac{1}{(1 - \alpha_1 \alpha_2)^2} \begin{pmatrix}
\sigma_{e,1}^2 + \alpha_1 \sigma_{e,2}^2 & \alpha_1 \sigma_{e,1} \sigma_{e,2} \\
\alpha_1 \sigma_{e,1} \sigma_{e,2} & \sigma_{e,2}^2 + \alpha_2 \sigma_{e,1}^2
\end{pmatrix},
\end{align*}
$$

(53)

$$
\begin{align*}
\Omega_y &= \frac{1}{(1 - \beta_1 \beta_2)^2} \begin{pmatrix}
\sigma_{\xi,1}^2 + \beta_1 \sigma_{\xi,2}^2 & \beta_1 \sigma_{\xi,1} \sigma_{\xi,2} \\
\beta_1 \sigma_{\xi,1} \sigma_{\xi,2} & \sigma_{\xi,2}^2 + \beta_2 \sigma_{\xi,1}^2
\end{pmatrix}.
\end{align*}
$$

(54)
The model at present is underidentified as there is a total of just 6 unique moments across the two samples, to identify the 8 unknown parameters

$$\alpha_1, \alpha_2, \beta_1, \beta_2, \sigma^2_{\alpha_1}, \sigma^2_{\sigma_2}, \sigma^2_{\xi_1}, \sigma^2_{\xi_2}.$$ 

In a study of the relationship between Mexican and Argentinian bonds, Rigobon (2002) identifies the model by setting $\alpha_1 = \beta_1$ and $\alpha_2 = \beta_2$. However, from (40), this implies that there is no contagion, just a structural break in the idiosyncratic variances. An alternative approach to identification which is more informative in the context of testing for contagion is to not allow for a structural break and set $\sigma^2_{\alpha_1,1} = \sigma^2_{\sigma_2,1}$, and $\sigma^2_{\alpha_1,2} = \sigma^2_{\sigma_2,2}$. Now there are 6 equations to identify the 6 unknowns. A test of contagion is given by a test of the over-identifying restrictions under the null hypothesis of no contagion. The observational equivalence between the two identification strategies has already been noted above in the discussion of the factor model. However, if the idiosyncratic variances are changing over the sample, the contagion test, is under-sized (Toyoda and Ohtani (1986)). One solution is to expand the number of asset markets investigated. For example, increasing the number of assets to $N = 3$ results in a just identified model as there are 12 unknown parameters $\alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2, \beta_3, \sigma^2_{\alpha_1}, \sigma^2_{\sigma_2}, \sigma^2_{\alpha_3}, \sigma^2_{\xi_1}, \sigma^2_{\xi_2}$, but there are now 12 moments as there are 6 unique moments from each of the variance-covariance matrices from the two sub-periods.

Another solution to the identification problem is to expand the model to include own lagged variables for example. In this case, the reduced form expressions in (52) represent VARs over the two sub-periods. Corresponding to each sample period, in each VAR there are 4 parameters associated with the lagged variables which are used to identify the 4 structural parameters. Favero and Giavazzi (2002) do this within a related context in testing for contagion; see Section 5.1 below.

Rigobon (2002) also suggests using instrumental variables to obtain consistent parameter estimates with the instruments defined as

$$s_i = i, -x_{i,1}, -x_{i,2}, \ldots, -x_{i,T}, y_{i,1}, y_{i,2}, \ldots, y_{i,T} \xi, \quad i = 1, 2.$$ 

This choice of instruments is an extension of the early suggestions of Wald (1940) and Durbin (1954). For example, Wald (1940) defined the instrument set as a dummy variable with a 1 signifying observations above the median and a $-1$ for observations below the median. In the case of contagion and modelling financial crises, observations above (below) the median can be expected to correspond to crisis (pre-crisis) observations. This suggests that the Rigobon instrument is likely to be more efficient than
the Wald choice as it uses more information.\textsuperscript{13} Rigobon then proceeds to estimate pooled equations as in (44), but with $\gamma_{i,j} = 0$. But this is not a test of contagion as $\alpha_i = \beta_i$ is imposed and not tested. Not surprisingly, the IV estimator of the structural parameters in this case, is equivalent to the matching moment estimator using (53) and (54) subject to the restrictions $\alpha_1 = \beta_1$, and $\alpha_2 = \beta_2$.

5 Models of Asymmetries and Nonlinearities

A number of papers have concentrated on modelling contagion through a range of asymmetrical adjustments. The motivation of these approaches is that the transmission processes across asset markets may be nonlinearly different during periods of extreme returns than during ‘normal’ times. In these models contagion arises when significant relationships across asset markets are detected during periods of extreme movements. The underlying differences in the proposed approaches lie in the ways that extreme observations are modelled.

To motivate the asymmetrical models of contagion as well highlight their similarities and differences with other contagion testing frameworks, consider the bivariate problem of testing for contagion from asset market 1 to asset market 2. Let the dynamics of the processes be represented by the first two expressions of the contagion model in (10)

\begin{align*}
y_{1,t} &= \lambda_1 w_t + \delta_1 u_{1,t} \\
y_{2,t} &= \lambda_2 w_t + \delta_2 u_{2,t} + \gamma u_{1,t},
\end{align*}

where contagion is represented by augmentation of the pre-crisis model for country 2, by unanticipated shocks from the asset market in country 1. Combining these expressions to substitute out $u_{1,t}$ from the equation for $y_{2,t}$ gives

\begin{equation}
y_{2,t} = \frac{\mu}{\delta_1} \left( \frac{\lambda_2 \delta_1 - \lambda_1 \gamma \delta_2}{\delta_1} w_t + \frac{\gamma}{\delta_1} y_{1,t} + \delta_2 u_{2,t} \right).
\end{equation}

As with the factor model, a test of contagion is still given by testing $\gamma = 0$, as it represents a test of the additional explanatory power of the asset market in country 1 in explaining movements in the asset market of country 2 in excess of the factors that govern movements in asset markets during non-crisis periods; namely, the market fundamentals ($w_t$) and idiosyncratics ($u_{2,t}$). Combining this equation with (55) yields a triangular system of equations. As $E[u_{1,t} u_{2,t}] = 0$, there is no simultaneity bias from

\textsuperscript{13}A similar issue arises in the Eichengreen, Rose and Wyplosz (1995,1996) framework in testing for contagion. This approach is discussed below in Section 2.4.2.
using least squares to estimate and test the model because of the model’s triangular structure.\textsuperscript{14}

Four models of asymmetries are now outlined. For each model, the treatment of $y_{1,t}$ in (57) or $u_{1,t}$ in (56) differs.

\section{Outliers}

Favero and Giavazzi (2002) use a VAR to control for the interdependence between asset returns, and use the heteroskedasticity and nonnormalities of the residuals from that VAR to identify unexpected shocks which may be transmitted across countries and hence considered contagion. The methodology first estimates a simple VAR and considers the distribution of the residuals. Residuals which contribute to non-normality and heteroskedasticity in the data are identified with a set of dummies associated with ‘unusual’ residuals for each country, indicating crisis observations. The test for contagion is then given as the significance of those dummies in explaining the returns for the alternate assets in a structural model. That is, the test for contagion is the significance of an unexpected shock in country \(i\) on the returns for country \(j\), a definition completely consistent with that given in the model of (55) to (57).

To highlight the properties of the Favero and Giavazzi (2002) testing framework, consider testing for contagion from $y_{1,t}$ to $y_{2,t}$. Define the dummy variable corresponding to an outlier in $y_{1,t}$, as

\begin{equation}
    d_{1,t} = \begin{cases} 
    1 : & |u_{1,t}| > 3 \delta_i^2 \\
    0 : & \text{otherwise}
    \end{cases}
\end{equation}

The Favero and Giavazzi test amounts to replacing $u_{1,t}$ in (56) by $d_{1,t}$

\begin{equation}
    y_{2,t} = \lambda_2 w_t + \delta_2 u_{2,t} + \gamma d_{1,t},
\end{equation}

and performing a t-test of $\gamma = 0$. To demonstrate their approach more formally, consider the following \(N\) variate first-order VAR model

\begin{equation}
    z_t = \Phi z_{t-1} + v_t,
\end{equation}

where $z_t$ are the pooled asset returns across the two sample periods as defined in (37), $\Phi$ contains the $(N \times N)$ VAR parameters and $v_t$ are the reduced form disturbances.

\textsuperscript{14}Of course, testing in the opposite direction changes the endogeneity/exogeneity status of the two asset returns, in which case the test is no longer valid. As with the Forbes and Rigobon (2002) approach, a simultaneous equations estimator is needed to be employed to correct for simultaneity bias.
with zero means and constant covariance matrix with variances given by $E[v_i^2] = \sigma_i^2$. The dummy variables are defined as

$$d_{i,t} = \begin{cases} 1 & : |v_{i,t}| > 3\sigma_i^2 \\ 0 & : \text{otherwise} \end{cases},$$

where one (unique) dummy variable is defined for each observation that is an outlier. These dummy variables are then included in a structural model which is effectively (44) without any scaling of the variables, augmented by the inclusion of own lagged variables to achieve identification. For a bivariate model where there is just one outlier in each returns series, the structural equations are

$$z_{1,t} = \alpha_{1,2}z_{2,t} + \theta_1 z_{1,t-1} + \gamma_{1,1}d_{1,t} + \gamma_{1,2}d_{2,t} + \eta_{1,t},$$
$$z_{2,t} = \alpha_{2,1}z_{1,t} + \theta_2 z_{2,t-1} + \gamma_{2,1}d_{1,t} + \gamma_{2,2}d_{2,t} + \eta_{2,t},$$

where $\theta_1$ and $\theta_2$ are the parameters on own lags and $\eta_{i,t}$ are the structural disturbances. A joint test of contagion is given by testing the significance of the shock in asset returns in the second (first) country on asset returns in the first (second) country

$$H_0 : \gamma_{1,2} = \gamma_{2,1} = 0.$$

This test can also be conducted individually to identify significant contagious linkages between countries 1 and 2.

The Favero and Giavazzi (2002) approach is very similar to the Forbes and Rigobon (2002) correlation test as both tests are based on testing the significance of dummy variables in an augmented model. In both cases the dummy variables are slope dummies: this is especially clear if the dummy variable in (60) is defined to equal the observation itself.\footnote{Defining the dummy variable this way changes the point estimates when estimating the structural model in (61), but not the value of the test statistic.} The similarities between the two testing frameworks are made more transparent by defining a crisis period to be where the dummy variable is non-zero. Observations when the dummy variables are not defined, by default correspond to pre-crisis periods. As the dummy variables are defined for a single observation, the parameter estimates of \{\(\alpha_{1,2}, \theta_1, \alpha_{2,1}, \theta_2\)\} in (61) can be computed simply by using pre-crisis data.

There are, however, two differences between the Forbes and Rigobon (2002) and Favero and Giavazzi (2002) approaches. Forbes and Rigobon identify a crisis period as a period of higher volatility using a single dummy which has a non-zero value during the entire crisis period. The Favero and Giavazzi test identifies potentially many (short-lived) crisis periods associated with extreme returns. Secondly, the Favero and Giavazzi
test assigns a different parameter to each dummy variable whereas the Forbes and
Rigobon is based on a single parameter to represent contagion between two countries.
This last property reflects that the two test procedures both represent Chow tests: the
Forbes and Rigobon approach is based on the covariance version of the Chow test,
whilst the Favero and Giavazzi test is based on the predictive version of the Chow test.

In implementing the Favero and Giavazzi (2002) test, the structural model needs to
be estimated using a simultaneous equation estimator to correct for simultaneity bias.
This correction appears to be adopted by Favero and Giavazzi. However, an important
assumption underlying this framework is that asset returns exhibit autocorrelation. If
this assumption is not valid, then the choice of instruments based on lagged returns
will not be valid, and identification of the structural model via the inclusion of own lags
will no longer be appropriate. Even if there is some autocorrelation in asset returns
it is not likely to be strong, resulting in weak instruments with the moments of the
sampling distribution of the test statistics possibly not existing.

5.2 Probability Models: Dichotomous Classifications

consider the transmission of contagion in currency markets across exchange rate regimes.
In order to accommodate all of the possible avenues for pressure on an exchange rate
they construct an Exchange Market Pressure Index (EMP). The EMP index is then
used to construct a binary CRISIS index which indicates whether or not a particular
currency is experiencing extreme pressure.

The Eichengreen et al (1995, 1996) framework for testing contagion can be inter-
preted as a variant of the dummy variable approach of Favero and Giavazzi (2002).
However, unlike the Favero and Giavazzi approach which requires constructing dummy
variables for the explanatory variables, in the Eichengreen et al approach a dummy
variable is also constructed for the dependent variable. To highlight the Eichengreen
et al approach, rewrite (57) by replacing the asset returns, \( y_{1,t} \) and \( y_{2,t} \), by dummy

\[ EMP_{i,t} = a \Delta e_{i,t} + b (r_{i,t} - r_{0,t}) + c (\Delta R_{i,t} - \Delta R_{0,t}), \]

(62)

where \( e_{i} \) is the log of the bilateral exchange rate, \( r_{i} \) is the short-term interest rate and \( R_{i} \) is the stock
of reserve assets. The weights, \( a, b \) and \( c \), are given by the inverse of the variance of the individual
component series over the sample period. Kaminsky and Reinhart (2000) adopt a different weighting
scheme whereby the weight on interest rates is zero.

23
variables

\[ d_{2,t} = \mu \frac{\lambda_2 \delta_1 - \lambda_1 \gamma}{\delta_1} w_t + \frac{\gamma}{\delta_1} d_{1,t} + \delta_2 u_{2,t}, \]  

(63)

where the dummy variables are defined in terms of large negative asset returns as\(^{17}\)

\[ d_{1,t} = \begin{cases} 
\frac{\gamma}{\delta_2} & : \quad y_{1,t} > f(EMP_{1,t}) \\
0 & : \quad \text{otherwise} 
\end{cases} \]  

(64)

\[ d_{2,t} = \begin{cases} 
\frac{\gamma}{\delta_2} & : \quad y_{2,t} > f(EMP_{2,t}) \\
0 & : \quad \text{otherwise} 
\end{cases} \]  

(65)

As the dependent variable is now binary, the model is respecified as a probit model

\[ y_{2,t}^* = \mu \frac{\lambda_2 \delta_1 - \lambda_1 \gamma}{\delta_1} w_t + \frac{\gamma}{\delta_1} d_{1,t} + \delta_2 u_{2,t} \]  

(66)

\[ d_t = \begin{cases} 
1 & : \quad y_{2,t}^* < f(EMP_{2,t}) \\
0 & : \quad \text{otherwise} 
\end{cases} \]  

(67)

where \( y_{2,t}^* \) is a latent normal random variable. The test of contagion, estimated by
the probit model in this instance, is again the significance of the parameter \( \gamma \) in (66).
Thus the Eichengreen et al (1995, 1996) approach can be viewed as focusing on
the change in the strength of the correlation during crisis periods. As the dummy variable
is defined for large (negative) movements, these correlations are based on the large
returns as compared to all returns as in the Forbes and Rigobon (2002) approach.

An important part of the Eichengreen et al (1995, 1996) approach is that it requires
choosing the threshold value of the EMP index for classifying asset returns into crisis
and non-crisis periods. As with the threshold value in (60) adopted by Favero and Giavazzi (2002), the empirical results are contingent on the choice of the threshold value.
In both the Eichengreen et al and Favero and Giavazzi approaches, this choice is based
on sample estimates of the data, resulting in potentially non-unique classifications of
the data for different sample periods\(^{18}\).

The construction of binary dummies in (64) to (67) in general amounts to a loss
of sample information resulting in inefficient parameter estimates and a loss of power
in testing for contagion. A more direct approach which does not result in any loss of
sample information is to estimate (57) by least squares and perform a test of contagion
by undertaking a t-test of \( \gamma \). In fact, the probit model of (66) to (67) delivers consistent
estimates of the same unknown parameters given in (57), but these estimates are

\(^{17}\)The CRISIS indicator in Eichengreen et al is constructed for the cases \( y_{i,t} > \mu_{EMP} + 1.5\sigma_{EMP} \),
that is a linear combination of the mean and standard deviation of the calculated EMP index. Other
relative weightings on the two components were trialed in their paper.

\(^{18}\)Both Eichengreen et al and Kaminsky and Reinhart use some matching of their crisis index
constructed using these thresholds to market events to validate the threshold choice.
inefficient as a result of the loss of sample information in constructing the dummy variables.

One of the attractions of the Eichengreen et al (1995, 1996) approach is that it generates probability estimates \( P_t \) of the spread of financial crises across countries. The change in the probability of a crisis is given by evaluating the probability at the two values of the dummy variable

\[
\frac{\partial P_t}{\partial d_{1,t}} = \Phi (z_1) - \Phi (z_0),
\]

where \( z_1 = \frac{\lambda_2 \delta_1 - \lambda_1 \gamma}{\delta_1} w_t + \frac{\gamma}{\delta_1} \) and \( z_1 = \frac{\lambda_2 \delta_1 - \lambda_1 \gamma}{\delta_1} w_t \). However, if the attraction of computing probability estimates of financial crises is the guide to model choice, such estimates can also be recovered by using (57). Adopting the assumption that \( u_{2,t} \) in (57) is normally distributed, the probability of a crisis in \( y_{2,t} \) is simply given by

\[
P (y_{2,t} < y^*) = \Phi (z),
\]

where \( \Phi (z) \) is the cumulative normal density evaluated at

\[
z = \frac{\mu}{\delta_2} y^* - \frac{\lambda_2 \delta_1 - \lambda_1 \gamma}{\delta_1} w_t + \frac{\gamma}{\delta_1} y_{1,t} / \delta_2,
\]

and \( y^* \) is a pre-assigned threshold variable.

Kaminsky and Reinhart (2000) find that the calculation of unconditional probabilities do not provide particularly useful information for predicting crises based on data across regions.

5.3 Probability Models: Polychotomous Classifications

Bae, Karolyi and Stulz (2003) concentrate explicitly on the tails of the distribution of asset returns by identifying the exceedances of individual returns and co-exceedances across asset returns. The exceedance at time \( t \), is simply the difference between a large (negative) asset return and some pre-assigned threshold value \( \text{THRESH} \). For two asset markets, the exceedances corresponding to large negative asset returns are\(^{19}\)

\[
E_{1,t} = \begin{cases} \frac{1}{2} : y_{1,t} < \text{THRESH} \\ 0 : \text{otherwise} \end{cases} \quad (68)
\]

\[
E_{2,t} = \begin{cases} \frac{1}{2} : y_{2,t} < \text{THRESH} \\ 0 : \text{otherwise} \end{cases} \quad (69)
\]

\(^{19}\)In extreme value theory, the exceedences are usually defined as \( y_{1,t} - \text{THRESH} \) when the threshold is reached. Butler and Joaquin (2002) find that the number of co-exceedances in the observed data exceeds that which could be generated from an underlying normal, GARCH or student-t distribution, consistent with their results on the correlation coefficients.
Comparing (68) and (69) with the Eichengreen et al (1995, 1996) dummy variables in (64) to (65), shows that the exchange rate market pressure indexes $EMP_{i,t}$ is equivalent to the threshold index used to identify exceedances. Bae, Karolyi and Stulz (2003) choose $THRESH = -5\%$, while Baur and Schulze (2002) extend this to consider a number of different thresholds endogenously.\footnote{Bae, Karolyi and Stultz (2003) also identify exceedences corresponding to large positive returns, in which case $THRESH = 5\%$.} A co-exceedance occurs at a point in time when $E_{1,t}$ and $E_{2,t}$ both exceed the threshold level

$$E_{1,t}, E_{2,t} = 1.$$ 

That is, both asset markets experience a large fall in asset values at the same point in time. For $N$ asset markets, categorising asset returns into co-exceedances yields a polychotomous variables which gives the number of co-exceedances occurring at each point in time. Bae, Karolyi and Stulz (2003) use a multinomial logit model to analyse the co-exceedances

$$P_{j,t} = \frac{\exp \left( \beta_j x_{j,t} \right)}{\sum_{k=0}^{N} \exp \left( \beta_k x_{k,t} \right)}, \quad j = 0, 1, 2, \cdots, N, \quad (70)$$

where $P_{j,t}$ is the probability that there are $j$ co-exceedances occurring at time $t$, and $x_{k,t}$ represent a set of explanatory variables used to explain asset returns and hence co-exceedances. The model is normalised by setting $\beta_0 = 0$, which corresponds to the case of no exceedances (ie no outliers). This is a natural extension of the Eichengreen et al (1995, 1996) framework which uses a probit model as it is based on a binary classification of asset returns.\footnote{Eichengreen et al (1995) in studying the transmission of crises also use a multinomial logit model.}

In a similar vein Kaminsky and Reinhart (2002) consider periods of turmoil to be due to extreme events, and also examine the 5th and 95th percentiles of the distribution and a multinomial logit framework. In their examination of the transmission of shocks between countries they distinguish between ‘weak form globalisation’ and ‘strong form globalisation’. The latter is somewhat similar to Bae, Karolyi and Stulz (2003) concept of co-exceedances involving contemporaneous extreme returns events in both countries. Weak form globalisation, however, considers the effect of a large shock in one country on another country, without imposing that the effects of the shock must also result in a large shock on the second country.

### 5.4 One-sided Asymmetries

Butler and Joaquin (2002) report that the change in correlations in asset returns between tranquil periods and crisis periods differs depending on the direction of the
crisis. In the case of positive shocks (bull markets) the difference in the correlations is broadly consistent with a model drawn from a normal distribution. However, for the crisis caused by negative shocks (bear markets) the rise in correlation between asset returns far exceeds that associated with a normal distribution. There seem to be nonlinearities in the behaviour of extreme shocks as proposed in the co-exceedance literature. To distinguish between positive and negative shocks, Dungey, Fry and Martin (2003) expand (56) as

\[ y_{2,t} = \lambda_2 w_t + \delta_{2} u_{2,t} + \gamma_+ u_{1,t} D_t + \gamma_- u_{1,t} (1 - D_t), \]  

where

\[ D_t = \begin{cases} \frac{1}{2} & : u_{1,t} > 0 \\ 0 & : \text{otherwise} \end{cases}. \]

A test of symmetry is given by

\[ H_0 : \gamma_+ = \gamma_- . \]

This is also the approach of Baig and Goldfajn (2000) (see also Ellis and Lewis (2000) and Kaminsky and Schmukler (1999)) in modelling equity returns in Brazil and Russia. Dummy variables are constructed which represent good and bad news in both Brazil and Russia (see Baig and Goldfajn (2000) for a list of dates) as follows

\[ D_{\text{bad},t} = \begin{cases} \frac{1}{2} & : \text{bad news in country 1} \\ 0 & : \text{no news} \end{cases} \]

\[ D_{\text{good},t} = \begin{cases} \frac{1}{2} & : \text{good news in country 1} \\ 0 & : \text{no news} \end{cases} . \]

The model is then given by

\[ y_{2,t} = \lambda_2 w_t + \delta_{2} u_{2,t} + \gamma_+ D_{\text{bad},t} + \gamma_- D_{\text{good},t} , \]

with a test of contagion from country 1 to country 2 given by testing

\[ H_0 : \gamma_+ = \gamma_- = 0 . \]

The studies mentioned so far concentrate on the asymmetric transmission of shocks in the level of the shocks. However, it is also possible that it is the asymmetric volatility of the shocks which matters - this is explored in Bekaert, Harvey and Ng (2003), who incorporate asymmetric GARCH in the idiosyncratic or country-specific shock of the latent factor model.

27
6 Additional Methods

6.1 Principal Components

Principal components provide an alternative way to identify factors; examples include Calvo and Reinhart (1995) and Kaminsky and Reinhart (2001). The principal components are based on an eigen decomposition of either the variance-covariance matrix or the correlation matrix, with the principal components computed as the eigenvectors associated with the largest eigenvalues. Thus, each computed principal component represents a weighted average of individual asset returns.

Principal component analysis is based on the assumption of a constant variance-covariance matrix. However, this assumption is unlikely to be appropriate when using high frequency asset returns data, especially estimated over a sample containing financial crises where volatilities may change over time.

6.2 Multiple Equilibria

An important feature of theoretical models of contagion is that they yield multiple equilibria (Dornbusch, Park and Claessens (2000)). This suggests that the underlying distribution is multimodal in general where the modes correspond to stable equilibria and the antimodes correspond to the unstable equilibria. In the case of two stable equilibria, these properties can be captured by a mixture distribution

\[ f(y_{i,t}) = \phi f_1(y_{i,t}) + (1 - \phi) f_2(y_{i,t}), \quad (73) \]

where \(0 < \phi < 1\) is a parameter which weights the individual densities \(f_i(\cdot)\) with means corresponding to the stable equilibria, to form the overall density. Jeanne and Masson (2000) adopt this strategy by employing Hamilton’s Markovian switching model (Hamilton (1994)), which is equivalent to (73) with a time-varying weighting parameter, \(\phi_t\), based on a Markovian updating formula; see also Masson (1999c) for a discussion of the approach.\(^{22}\)

6.3 Spillovers

A number of papers undertake measurements of contagion where contagion is not identified as the effects of foreign unexpected shocks on a domestic asset return. In particular, transmissions through an identified channel such as fundamental variables or

\(^{22}\)Lim and Martin (1999) use another approach based on a generalised normal distribution to capture multimodality.
financial streams are more consistent with the concept of spillovers in the terminology of Masson (1998,1999a,b). For example, Glick and Rose (1999) and Dasgupta (2001) consider contagion as the spread of a crisis from its origin by any means, and the examples they give of competitive devaluation and trade links are easily incorporated into current concepts of anticipated linkages, and therefore more consistent with notions of spillovers than contagion. In a similar vein van Rijikghem and Weder (2001) consider financial flows. A further example is Lowell, Neu and Tong (1998) where contagion is assessed by examining the effects of lagged values of foreign asset returns on domestic asset returns. Trade links are often associated with the location of countries. A strong working hypothesis in the crisis literature is that crises seem to have strong regional features. This has been investigated using gravity models in Kaminsky and Reinhart (2002) and Bayoumi, Fazio, Kumar and MacDonald (2003) who make the case that geographical relationships matter, and Dasgupta (2001) who finds that regions are less important.

However, Kiyotaki and Moore (2002) present the case of known ex-ante linkages through balance sheets, but argue if these are sufficiently complex they may not be fully anticipated, but behave as contagion. A related channel of contagion is information flows and investor preferences. Empirical work on this stream of research is limited to calibration and simulation experiments, due to the obvious lack of data. However, the ideas include the search costs of obtaining information and the role of increasing global integration across asset markets. Calvo and Mendoza (2002) and Chue (2002) provide simulations of theoretical models which show how contagion can spread through information flows and investor preferences. Rigobon (2002) in an application of the correlation tests discussed in section 4 to Latin American markets, shows that the upgrading of Mexican debt ratings dramatically changed the characteristics of the Mexican markets to move it away from its previous common regional association with other Latin American countries.

6.4 Multiple Classes of Assets

The majority of the existing literature on contagion considers transmissions across geographical borders for a particular asset market, although one important exception to this is the relatively large literature discussing joint banking and currency crises such as Kaminsky and Reinhart (1999) and Bordo and Eichengreen (1999). There have been a number of applications of similar techniques to the same data period and different asset markets across country borders; such as Baig and Goldfajn (1999) and Ellis and Lewis (2000) which look at currency, equity and bond markets in a correlation
and VAR framework. Dungey, Fry, Gonzalez-Hermosillo and Martin (2002) look at contagion in developing market bonds during the Russian and LTCM crisis, and then at the equity markets for the same period in Dungey, Fry, Gonzalez-Hermosillo and Martin (2003). None of these papers formally model the linkages between the different asset classes during the crisis. Kaminsky and Reinhart (2001) consider coincidence in dates of the greatest movements and of shocks in univariate conditional volatility estimates, somewhat similar in idea to the co-exceedances of Bae, Karolyi and Stulz (2003).

There is a rich empirical finance literature modelling the interactions of several markets jointly. For example, Bekaert and Hodrick (1992) consider the common and idiosyncratic factors determining equity and currency markets in a modelling framework related to that used in DFGM. In the context of modelling contagion, McKibbin and Wilcoxen (1998) emphasise the importance of studying the linkages across markets of different classes of assets as they argue that the East Asian crisis originated in the equity markets and then transmitted to currency markets. However, there is very little empirical literature which identifies and tests these additional linkages. Some exceptions are Granger, Huang and Yang (2000), Kaminsky and Reinhart (2001), Fang and Miller (2002) and Dungey and Martin (2001). Granger et al conduct Granger causality tests across pairs of assets and borders and find evidence of dual causality. Kaminsky and Reinhart find a relatively large component of variance in overnight interest rates, stock returns, exchange rate changes and bond spreads can be attributed to an initial principal component across a wide sample of countries in 1997-1999. Fang and Miller (2002) use a bivariate GARCH model to examine the effects of currency depreciation on equity market returns in East Asia and Dungey and Martin (2001) find evidence of contagion from equity to currency markets in the East Asian crisis.

Some of the difficulties in modelling transmission across financial assets include controlling for different time zone issues, data frequency and volatility structures across both country and asset types. This could potentially increase the complexity of the modelling problem, and result in issues of dimension, these issues are discussed in an earlier version of this paper.23

23The earlier version is available at http://rspas.anu.edu.au/economics/staff/dungey/. This current paper contains the technical material from the previous version.
7 Conclusions

This paper has overviewed a number of the important tests for the presence and characteristics of contagion in financial markets in the current literature. Using an overarching framework of a latent factor model, similar to that proposed in the finance literature, the different test methodologies are shown to be related. In essence each method is shown to be a test on a particular parameter regarding the transmission of a shock from one country or market to another, the parameter $\gamma$ in the exposition of this paper.

The five tests of contagion specifically considered in the paper were first the latent factor framework developed by the current authors, and similar to that of Corsetti, Periocoli and Sbracia (2001) and Bekaert, Harvey and Ng (2003) in which testing for contagion is a test on the parameter $\gamma$. Second, the relatively popular correlation approach associated with Forbes and Rigobon (2002) was also shown to be a test on the parameter $\gamma$ within the latent factor framework. Third, the test of Favero and Giavazzi (2002) based on using a VAR to identify unusual events and then testing the potential transmission of these events in a structural framework, was transformed to be a reorganisation of the latent factor model and the contagion test consistent with a test on the parameter $\gamma$. Fourth, the probability based framework of Eichengreen, Rose and Wyplosz (1995,1996) which tests for contagion as a non-zero probability of associating foreign crises with a domestic crisis was shown to have a similar form in the latent factor model to the previous test, but with alternate conditioning information. Finally, the extreme returns test of Bae, Karolyi and Stulz (2003) is a further refinement of the Eichengreen et al framework, and hence can be similarly cast in a latent factor model and expressed as a test on the parameter $\gamma$.

Whilst the paper has drawn together many of the existing empirical methods to identify contagion there are many further questions to be addressed. In a companion paper to this one we address the issues of time zones, data frequency, missing observations and endogenous definitions of crisis periods. In addition, issues associated with the practical implementation of the tests described here are discussed. Many other areas remain to be explored; for example the small sample properties of the tests outlined here, and their performance in detecting contagion across a range of financial crises. These problems are part of our current and ongoing research agenda.
